Petrochemical Technology

Chemicals from Propylene

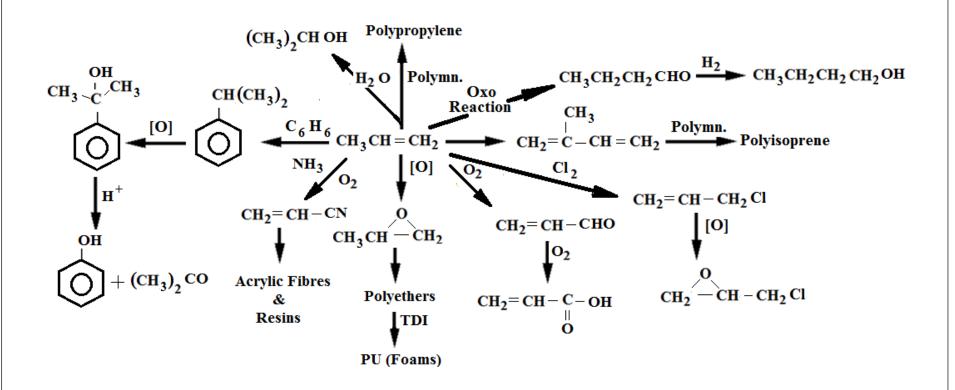

Propylene Consumption Patterns

Global propylene capacity could increase from 150.3 MTPA in 2023 to 199.35 MTPA in 2030.

India Polypropylene market demand stood at 5.9 Million Tonnes in FY2023 and is forecast to reach 10.29 Million Tonnes by FY2030, growing at a healthy CAGR of 7.25% until FY2030.

Major Chemicals form Propylene

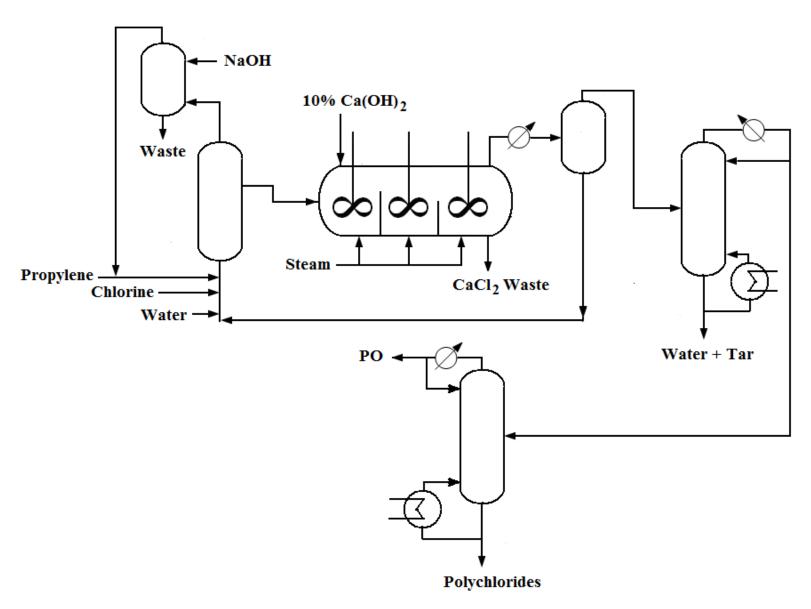

Propylene Oxide

Chemical Reactions

(a) Chlorination
$$50 \circ C$$
 Cl
CH₃CH = CH₂ + Cl₂ + H₂O \longrightarrow CH₃CH CH₂OH + HCl

(b) Dehydrochlorination

Flowsheet for the Production of Propylene Oxide

ACRYLONITRILE (CH₂=CH-CN)

Ammoxidation of propylene to acrylonitrile is usually carried out in fluid-bed reactors converting a nearly stoichiometric mixture of propylene, air and ammonia at about 400-500°C, 1.5-3.0 atm pressure. Practically complete conversion of propylene and ammonia is achieved to produce acrylonitrile in 65-75% selectivity. Acetonitrile and HCN are the main byproducts. The Sohio process originally used Oxides of Bi, Co, and Mo, and bismuth and cobalt molybdates. Other catalysts developed later (uranyl antimonite, antimony oxide-iron oxide, oxides of Fe, Ce, and Mo, mixed oxides of Sb and Sn) produce fewer byproducts and ensure higher yields of acrylonitrile.

Silica supported oxides of Selenium, Iron and Tellurium have also been used as catalysts. It gives 100% conversion of propylene with 86.9% selectivity for acrylonitrile and 2.9% selectivity for HCN in 2-5 s of contact time at 320 °C.

Main Reaction:

CH₃-CH =CH₂ + NH₃ + 1.5 O₂
$$\rightarrow$$
 CH₂=CH-CN + 3H₂O
 Δ H = -123.2 kcal/mol

Side reactions in ammoxidation process:

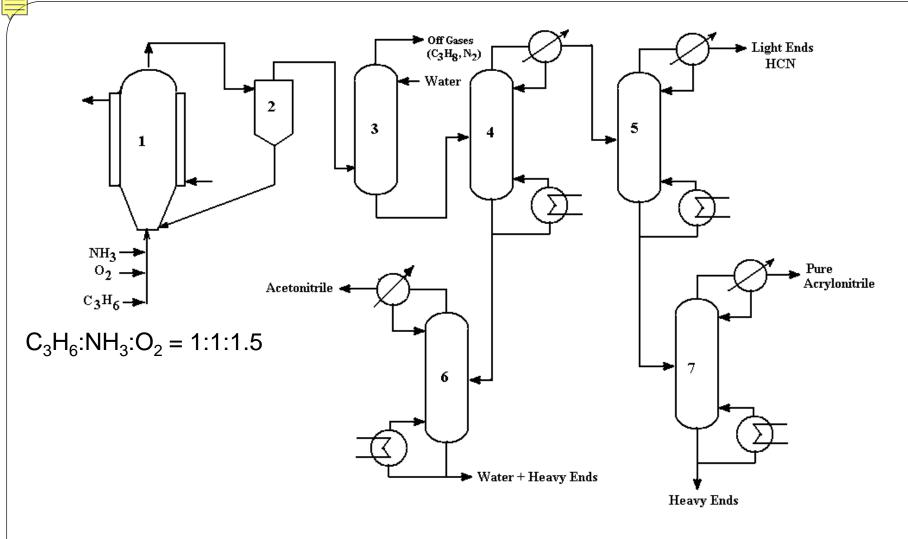

CH₃-CH =CH₂ + NH₃ + 2.5 O₂
$$\rightarrow$$
 CH₃CN + CO₂ + 3H₂O
CH₃-CH =CH₂ + NH₃ + 2 O₂ \rightarrow HCN + CH₄ + CO₂ + 2H₂O
CH₃-CH =CH₂ + O₂ \rightarrow CH₂=CH-CHO + H₂O
CH₂=CH-CHO + 0.5 O₂ \rightarrow CH₂=CH-COOH
CH₃-CH =CH₂ + 4.5O₂ \rightarrow 3CO₂ + 3H₂O

Propane Ammoxidation – BP Process

Processes based on propane ammoxidation to manufacture acrylonitrile have also been developed and commercialized by BP. Dehydrogenation at high reaction temperature (485-520 °C), which is about 100 °C higher than that for propylene ammoxidation, results in the formation of propylene, which subsequently undergoes normal ammoxidation.

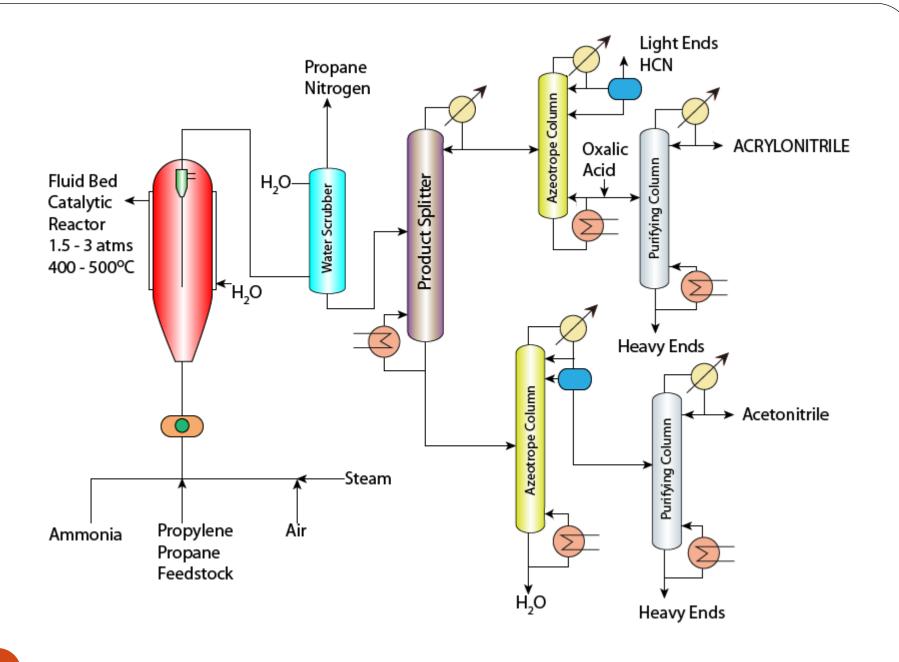

Despite higher investments and markedly lower selectivity (30-40%), the process can be economical because of the price difference between propylene and propane.

Better selectivities can be achieved at lower (40-60%) conversions.

Acrylic Acid from Propylene

$$CH_3CH = CH_2 \xrightarrow{O_2} CH_2 = CH - CHO \xrightarrow{0.5 O_2} CH_2 = CH - C - OH$$

The two-step process yields acrolein as an intermediate that can be isolated, if desired. Optimum catalyst and temperatures are different for each of the two steps, the first step requiring much higher temperature than the second.

Molybdenum based catalysts predominate and a typical catalyst for the first step of the two-step conversion is $Fe_4BiW_2Mo_{10}Si_{1.35}K_{0.6}$. With the catalyst at 320 °C, propylene conversion is 97% and acrolein selectivity is 93%. In addition, however, there is a 6% selectivity to acrylic acid making the useful selectivity 99%. These results are typical of what can be achieved with modern sophisticated catalyst.

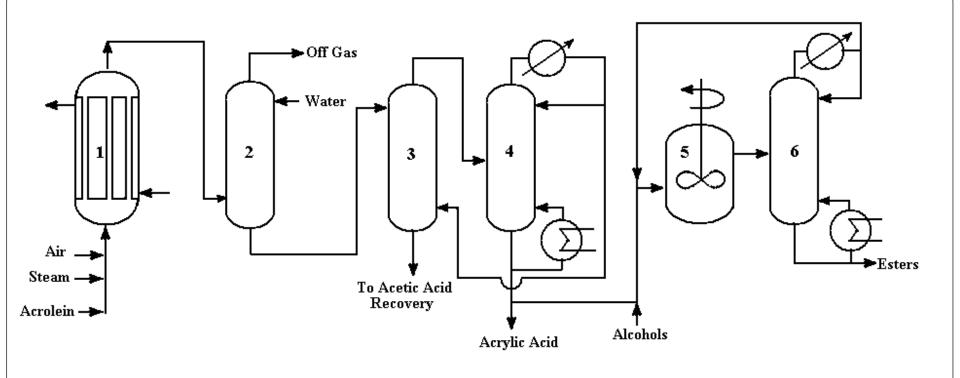

In the second stage, the catalyst used is $Mo_{12}V_{4.6}Cu_{2.2}Cr_6W_{2.4}$. The catalyst is supported on alumina and at 220 °C, a 98% selectivity for acrylic acid is obtained.

Flow sheet for the production of acrylic acid/acrylates from acrolein

The most important use of acrolein is for the production of D,L-methionine, an essential amino acid added to poultry feeds. Methionine is the amino acid produced in third largest volume after L-glutamic acid, whose monosodium salt is a flavor enhancer in foods, and L-lysine, also used in feeds. In the methionine synthesis, acrolein reacts almost quantitatively with methyl mercaptan in the presence of pyridine to yield β -methylthiopropionaldehyde. The aldehyde is converted to a hydantoin with sodium cyanide and ammonium carbonate. Hydrolysis of hydantoin with aq. NaOH gives sodium salt of methionine, which on acidification produces methionine.

Oxo Process

An oxo process involves the substitution of HCHO across a double bond, hence the name **Hydroformylation**. The reactants are an α -olefin and synthesis gas (CO + H₂). The primary product is an aldehyde with one additional carbon atom. The process is capable of producing the following compounds of commercial interest:

(a) Long chain alcohols:

Isooctyl alcohol – used in the synthesis of dioctyl phthalate, a plasticizer for polymers, principally polyvinyl chloride.

Decyl alcohol – made from nonene, a trimer of propylene; sulfated straight chain derivative is a good biodegradable detergent; esterified for plasticizer use.

Tridecyl alcohol – made from dodecene, a tetramer of propylene; sulfated derivatives used for detergents.

(b) Short chain alcohols:

- *n-Butanol* plasticizer; converted to butyl acetate and other solvent derivatives
- **2-Ethyl** hexanol dimerized via butyraldehyde, used in platicizers and synthetic lubricants.
- (c) *n-Butyraldehyde* converted to butyric acid and anhydride for making cellulose acetate butyrate, a high strength thermoplastic; reacts directly with polyvinyl chloride to make polyvinyl butyral film, used for safety glass.

Butyraldehyde and n-Butanol from Propylene: Oxo Process

The olefin in the liquid state is reacted at 250-300 atm and 150-170 °C in the presence of a soluble cobalt catalyst (usually, cobalt carbonyl).

The aldehyde and lesser amount of alcohol are formed.

With the Co-catalyst, the ratio of n- to i- isomers of aldehyde is 3-4:1.

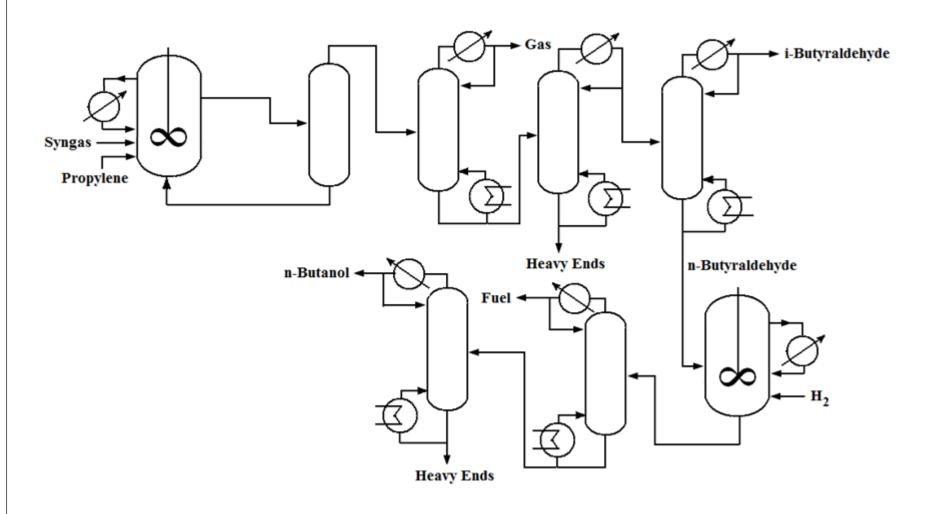

Improved catalyst like Wilkinson catalyst (Triphenyl phosphine and Rhodium chloride, $PPh_3/RhCl_2$) has been developed which gives more normal isomer in the ratio of 10:1 under milder operating conditions (100 $^{\circ}$ C, 10-20 atm).

The normal aldehyde is separated and hydrogenated to the desired n-Butanol.

$$CH_3CH = CH_2 + CO + H_2 \xrightarrow{150-170 \text{ °C}} CH_3CH_2CH_2CHO + (CH_3)_2CHCHO$$

$$CH_3CH_2CH_2CHO + H_2 \xrightarrow{Ni Cat.} CH_3CH_2CH_2CH_2OH$$

Overall Rate and Influence of Reaction Parameters to Selectivity and Reactivity

$$\frac{d[aldehyde]}{dt} = k_{obs}[alkene][H_2][Co][CO]^{-1}$$

If a 1:1 H_2/CO ratio is maintained, the rate will be independent of total pressure, since the rate is proportional to pH_2 and inversely proportional to pCO. However, a certain minimum CO partial pressure is required to maintain the stability of $[CoH(CO)_4]$, which decomposes to cobalt metal at low pCO. Thus, reasonable reaction rates in the temperature range 110–180 °C require rather high CO partial pressures (pCO), and total H_2/CO pressures of 200–300 bar.

Disadvantage: high CO partial pressure decreases the hydroformylation reaction rate.

Advantages: high pCO increases linear:branched ratio, decreases alkene isomerization.

→ Compromise between rate and regioselectivity!

Isobutyraldehyde is used to make neopentyl glycol, which is used largely in unsaturated polyester synthesis to enhance alkali resistance of the cured product.

$$(CH_3)_2$$
СНСНО + НСНО \longrightarrow $(CH_3)_2$ С-СНО $\xrightarrow{H_2}$ $(CH_3)_2$ С-СН2ОН CH_2 ОН CH_2 ОН Neopentyl glycol

2-Ethyl hexanol is produced by the aldol condensation of n-butyraldehyde. The reaction occurs in presence of aqueous caustic soda and produces 2-ethyl-3-hydroxyhexanal. The aldehyde is then dehydrated and hydrogenated to 2-ethyl hexanol.
